Where in the queue is my job, and why?

The simplest queuing algorithm is “first come, first served”. The queuing of jobs on the HPC cluster is a little more sophisticated as we pursue several goals:

- Minimal queuing times, especially for short jobs. Nobody wants to spend 4 hours in the queue for a 1-hour job.
- Efficient use of the available resources. If there is a job ready which can use hardware that would otherwise be idle, run it, even if it’s not next in the queue.
- Fair use of resources. If you’ve made heavy use of the cluster recently, jobs belonging to a user who has had less CPU time will get higher priority.
  At NYU “recently” means “the last 24 hours”, so users with large workloads are not excessively penalized.

Moab supports these goals by calculating a priority for each submitted job and placing the job in the queue according to its priority. The schedule of which job will run where and when is built from the job queues. When a job finishes earlier than scheduled (due to an overestimated walltime request), Moab attempts to fill the newly-available space by scanning the queue for the first job which will fit without delaying an already-scheduled, higher priority job. In this way low-priority jobs with smaller resource requirements can jump ahead and be run early.

Monitoring jobs with qstat

The qstat command is described in more detail here.
